## PART I

### THE SHORELINE EROSION STUDY

#### A. INTRODUCTION

Virtually every owner of waterfront property in Tidewater Virginia has gained an awareness of the importance of the problem of shoreline erosion either through the loss of his own property or through his observations of other properties. The problem is particularly acute for the homeowner who watches the reduction in the width of the fast-land buffer between his home and the water. Aside from this obvious importance of erosion relative to the wasting of valuable land, the eroded materials also constitute a significant fraction of the total sediment introduced into the Chesapeake Bay system. The silts and clays eroded from the shoreline move into the deeper water and contribute to the general siltation problem. Most of the sands and gravels are left near the shoreline to form beaches or to accumulate in forms such as spits. The accumulations are at times troublesome if they block navigable channels to tributaries.

As the population is growing more rapidly in the coastal zone than in any other segment of the nation, the pressures on utilization of the shorelands also increase. As these pressures may become more severe, there is a need for planning the utilization of the limited resource of the shorelands. Without planning, the very elements which attract people to the shore may be destroyed by incompatible utilization. One part of the knowledge required for enlightened planning is the determination of how the shoreline is behaving in response to the natural forces exerted on it.

The need for shore erosion studies in the Chesapeake Bay system has long been recognized. As early as 1949 erosion information was compiled for the State of Maryland (Singewald and Slaughter, 1949). In 1962 an erosion survey was conducted in Virginia for the tidal Rappahannock River and part of the Potomac (Virginia Tidal Riverbank Erosion Survey). The survey included a limited economic analysis of the affected shoreline. The present study is the first comprehensive evaluation of erosion for the entire Virginia Chesapeake Bay

system. The study does not include the ocean shoreline as that is currently under study and will be the subject of a future report.

The objective of this report is to provide a source of information about shoreline erosion that can be utilized by the public at large as well as by those county, state, and federal agencies which are concerned with the problems of shoreline erosion. Consideration of the erosion problem is an essential element in planning shoreland utilization.

The basic informational elements used in this study were a topographic map series of the 1850's and the 1940's. Comparisons were made of the high water shoreline positions at the two times, with measurement consisting of areal changes for individual small segments of the coastline. The derived statistics are thus averages over a rather long term. These are very useful data but they do mask the short term variability in the erosional processes. The user must have this fact in mind.

#### ACKNOWLEDGEMENTS

The study was funded by National Science Foundation, Research Applied to National Needs Program (RANN) Grants GI 29909 and 34869 to the Chesapeake Research Consortium, Inc. (Virginia Institute of Marine Science, The Johns Hopkins University, The University of Maryland, and the Smithsonian Institution). The compilation of the erosion data in this study was a large undertaking. Our task could not have been completed within the prescribed time had it not been for the generous assistance provided by the administration of the NASA-Langley Research Center in allowing the use of their X-Y digitizer. We most gratefully acknowledge this assistance.

The basic computer program for the calculation of area changes, shoreline length, and derived parameters was written by Hayden Gordon of V.I.M.S. Mr. Ashbury Sallenger, a graduate assistant, assisted in all phases of the study.

In addition, we acknowledge the wholehearted and professional work of Ken Thornberry and Bill Jenkins of the photo lab, Russell Bradley, Joe Gilley, Kaye Stubblefield, and Jane Davis of the art room. Finally, we thank Gaynor Williams for final composition and Beth Marshall for typing the report.

## B. SHORE EROSION PROCESSES IN TIDEWATER VIRGINIA

Shore erosion is the process of detachment and transportation of sediment particles from the shore, resulting in the landward retreat of the land-water boundary. Although this process can be caused by wind action and the surface runoff of water, the most significant erosion agent on the shoreline of the Chesapeake Bay system is the action of wind waves. In many locations the tidal currents combine with the wave action to accelerate the process of transport of material from the site of erosion. Superimposed upon the active forces of waves, currents, runoff, and wind, another factor must be considered, specifically, the slow rise in sea level relative to the land. This is due to an increase in water volume from the slow melting of glaciers and/or the local absolute change in the land's elevation due to geological processes. This increase in sea level translates the erosive power of the waves further inshore.

The degree of shoreline recession which a particular site experiences is dependent upon many factors. The major factors are:

1. The intensity of wave action and the exposure to strong tidal currents.
2. The character of the sediments at the site and the degree of protection offered by vegetative cover, specifically marsh grass, at the shoreline.
3. The supply of sand moving along the shoreline from other eroding areas or from streams along the shoreline.
4. The gradient or slope of the fastland adjacent to the shoreline and the slope of the nearshore bottom.

Within the Chesapeake Bay and its tributary estuaries (e.g. James River) the dominating erosion agent is the waves generated by local wind action. The growth and height of the waves is controlled by four factors: the over water distance over which the wind is blowing, known as the fetch; the speed of the wind; the duration of the wind; and the depth of water.

Due to the weather patterns affecting the

region, the peak winds occur during storms and the passage of fronts. For example, the northeast storms during the fall, winter and early spring generate winds, and therefore local waves. These winds and waves attack the western shore of the Bay and those tributary shorelines with a fetch to the northeast or east. The winds and low pressure along the ocean coastline have an additional, indirect, effect on the Bay system. The storms force additional water into the Bay. Frequently this local "wind tide" or storm surge may be one or two feet above the normal tide level. For example, in the March, 1962 storm, water elevations at Norfolk Harbor were 6.1 feet higher than predicted. Similar surge heights can occur during the passage of hurricanes (U.S. Army Corps of Engineers, 1970). When this occurs, the wave driven erosional action is concentrated higher on the fastland, above the usual beach which acts as a buffering zone in normal circumstances. In addition to surge forced into the Bay the local winds tend to push water against the shoreline which further enhances the water elevation. This is known as wind set-up. After the storm front has passed the winds frequently shift to the northwest quadrant. The eastern shore of the Bay is then exposed to intense wave action. Again the wind set-up raises the water elevation, resulting in the wave activity being concentrated above the usual beach level. These effects of storms are, of course, further enhanced if they occur in conjunction with the higher tides during the lunar month.

The orientation of the tributary estuaries, the James, York, Rappahannock and Potomac Rivers, is approximately northwest-southeast. This fact increases the vulnerability of their shorelines to intense wave action generated by winds from the northwest quadrant. Due to these winds, the south sides of these tributaries experience somewhat greater erosion than the north. The regional summer winds, with a dominant southerly and southwesterly direction, generate waves which attack the northern shores of the estuaries.

In addition to the height of the waves, the direction at which they impinge on the shoreline controls the magnitude of transport along the shoreline. This is central to the question of shoreline stability. Let us consider a hypothetical case of a shoreline several miles in length where the fastland is a cliff composed of a mixture of stratified gravel, sand, silt, and clay,

a situation which is typical of much of the Virginia shoreline. Under wave attack, particularly if the water level is high due to the tide or storm surge, the cliff material itself may be undercut causing slumping of the face material. Continued wave action on the slumped material would winnow away the silts and clays leaving the sand and gravel to form a beach deposit. Part of the sand and gravel on the beach will be transported along the beach (longshore drift). The beach itself acts as buffer to wave energy as the waves break and run-up and back down the sloping foreshore. If there is sufficient sand drifting down the shore zone from the up-drift segment of the coast, the beach at any given site may remain full enough to cushion the effects of a particular storm. If, however, the sand supply up-drift is stopped, the buffer effect is reduced and erosion will ensue. Along the Virginia shoreline, waves approach from more than one direction at different times so that longshore drift occurs in both directions. However, in most cases there is a predominance of drift in one direction.

Much of the sand drifting along the Virginia coastline ultimately is deposited as spits or bars in front of lesser tributary creeks where it may contribute to choking of the entrance channel.

Marsh grass along the shoreline has a very beneficial influence in hindering erosion as it acts, through its root system, to bind the substrate while the grass itself slows the water flow and traps sand. Whenever possible, natural stands of grass should be untouched. Research is in progress to develop means of planting marsh grass for erosion protection; but, for the most part, this strategy has proved unsuccessful in areas receiving intense wave attack.

The erosional behavior of any particular segment of shoreline may be expected to vary from year to year depending upon the frequency and intensity of storms. Furthermore, similar variations may also arise from differences in the average mean sea level elevations, even though the long term (decades) trend is for a relative rise in sea level. In the lower Chesapeake Bay the long term trend is about 0.01 feet per year (Hicks, 1972). However, yearly variations of 0.15 feet per year are not uncommon. Although these differences are small they can be significant in terms of horizontal distances across a

gently sloping shore. The long term trend has dramatic consequences.

The role played by beaches in the physical processes of the coastline merits reiteration: beaches are natural land forms which serve to absorb incident wave energy thereby inhibiting erosion of the fastland. The details of the configuration of any given beach may change hour by hour or day by day as the accumulation of sand adjusts to changing conditions. By and large, the natural maintenance of beaches along Virginia's Chesapeake Bay system shoreline is attained at the expense of erosion of the fastlands. For any particular segment of shoreline, the source of sand is derived from an updrift erosion site or from erosion of fastland at that site itself. These factors are an essential consideration in the philosophy and strategy in planning erosion control programs.

### C. METHODS AND MEASUREMENTS

**METHODS.** The first step of the work consisted of transferring the high water shoreline position from the older topographic map series to the later map series. The earlier map series was that of the Coast and Geodetic Survey performed in the 1850's while the later series was that of the U.S. Geological Survey performed during the period 1950 to 1968. All maps were rectified to a scale of 1:20,000 using stable base film positives. After both shoreline positions were on one map it was possible to identify sections of the shoreline where erosion or accretion had occurred. Each of these elemental sections, termed a reach, was numbered and its end points marked. In addition, note was made whether the shoreline consisted of marsh or beach. The end points of the reaches were chosen at identified map points whenever possible as long as it did not compromise the primary criterion. In all, 1,725 reaches were identified and measured.

Changes in shoreline position in the smaller tidal creeks were not included as some limit on the level of detail had to be set. The cut-off point for measuring the length of the shoreline was chosen as that point where the channel width narrowed to 150 feet.

Some areas of the shore lacked either one or the other of the surveys. Thus, of a total measured shoreline length of 2,951 miles, erosion characteristics were measured for 2,366 miles. The remainder, 585 miles, represents the shoreline length not assessed for erosion.

Islands and some of the more crenulated creeks required a somewhat different approach. In most cases there were no distinct reaches apparent when comparing an island's older and more recent shoreline positions. For these cases only the area change and new shoreline length were calculated. In complex creek systems which had many small areas of erosion or accretion the system was treated as a whole, again simply noting the net area change and the shoreline length.

Fig. 1 - Schematic Presentation of Parameter Definition

The following parameters were measured or calculated for each reach (see Figure 1):

- Area Change, A**, in acres, represents the area enclosed between the newer and older shoreline positions. Each reach is identified as to whether the change was erosion or accretion.
- Length of Shoreline, L**, is expressed in thousands of feet, for example, 3,200 feet reads as 3.2. The shoreline used in this measurement was that delineated on the more recent map.
- Mean Erosion or Accretion Distance, R**, is expressed in feet. This parameter is calculated by dividing the area by length of shoreline.
- The Average Rate of Erosion (or Accretion), E**, is expressed in feet per year. This parameter was calculated by dividing the mean erosion distance by the time in years between the applicable surveys.
- Height of Fastland (or Marsh)**, is expressed in feet. This parameter has considerable uncertainty since it was estimated from topographic maps with a contour interval of 5 to 20 feet. In some cases there was appreciable variation in elevation within a reach which necessitated another estimate of the average elevation. Marsh was considered to be three feet in height.
- Volume Eroded or Accreted, V** is expressed in cubic yards. This parameter was calculated by multiplying the area and the height of the fastland with subsequent conversion to cubic yards.
- The Volume Coefficient** is the expression used to normalize the volumes to a 100 year base. It was obtained by dividing the time span between the maps used a particular reach into 100.
- The Adjusted Volume** is the calculated volume lost or gained over a 100 year period. This is obtained by multiplying the volume coefficient by the unadjusted volume.

The measurement of area and shoreline length for each reach were made with an electronic X-Y digitizer with punch card output. Tests of reproducibility indicated a precision of + 1% in area and even smaller differences between operators on the same machine. A computer program was written to calculate the area and the above output parameters.

The compilation of summary statistics for any given county raised a problem since our basic erosion information was based on variable time periods. For example, part of the measurements may have been made from surveys spaced 90 years apart while the other part was from surveys with a 70 year time span. Meaningful statistics for the entire county cannot be made simply by combining or averaging the time span. To circumvent this problem, the data for all reaches were normalized to 100 years. Thus, if a given reach lost 75 acres over 75 years it is assumed that the loss for 100 years is 100 acres. The assumption, then, is that the rate of loss (or accretion) is constant. Most people living along the shoreline and certainly those working in coastal processes realize this is a tenuous assumption since they will observe significant variations in the rate of loss from year to year depending upon the frequency and intensity of storms. However, such statistics do have meaning for planning and shoreline management purposes on a broad scale since relative differences in the severity of erosion will clearly show.

The distribution of the time span between surveys was as follows:

Number of Quadrangles	Time Span Between Surveys
46	99 to 90 years
23	89 to 80 years
19	79 to 70 years
8	69 years
3	54 years
1	40 years

D. ORGANIZATION OF THE REPORT

Since this report is intended to provide useful information for a wide audience, ranging from individual property owners to state and federal management agencies, the data for each shoreline reach investigated is included.

The entire Bay system was divided into eight sub-systems as shown in Figure 2. These are:

- Chesapeake Bay Eastern Shore (CBES)
- Chesapeake Bay Western Shore (CBWS)
- Chesapeake Bay Southern Shore (CBSS)
- James River up to Richmond
- York River up to West Point
- Piankatank River
- Rappahannock River up to Fredericksburg
- Potomac River up to Fairfax County.

Within each of these sub-systems the individual shoreline reaches were numbered sequentially. Summary results have been compiled for each sub-system and for each county having tidal shoreline exposure.

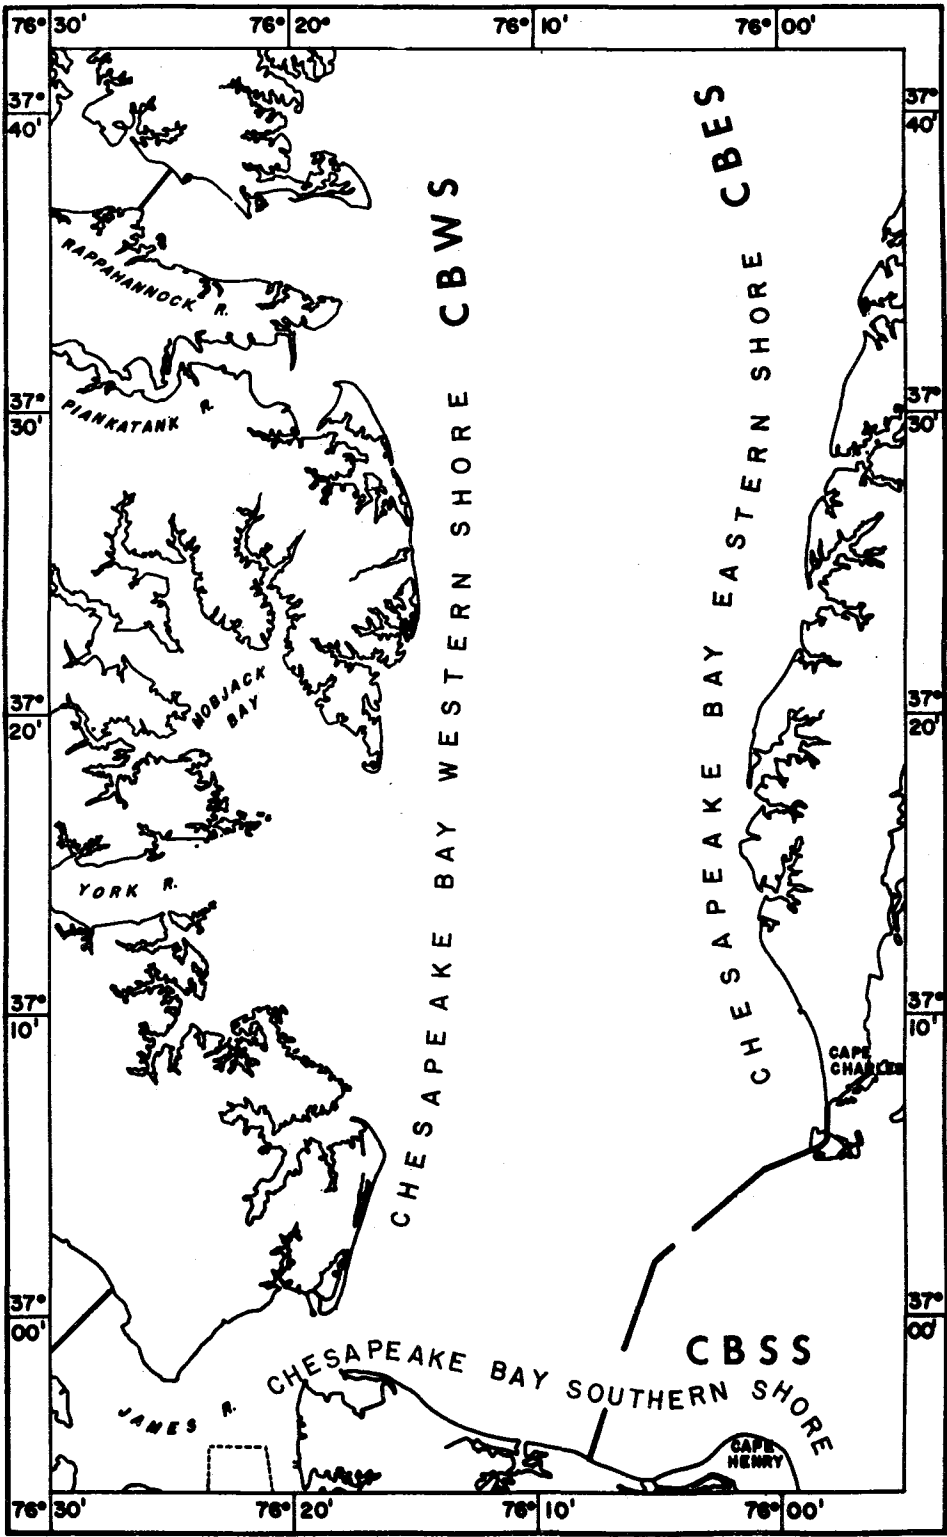

Fig. 2 - Location of Subsystems

## PART II

### RESULTS OF THE STUDY

#### A. SUMMARY STATISTICS

##### 1. Summary of Shore Erosion in Tidewater Virginia

The shore erosion measurements for Tidewater Virginia, excluding the ocean shoreline, are summarized in Table 1. As mentioned previously the results of acreage and volumes of material lost have been prorated to a base time of one hundred years. Inspection of Table 1 indicates that over 21,000 acres of land had been lost due to erosion over a 100 year period over a shoreline length of approximately 2,400 statute miles. This gives an average loss of about nine acres per mile of shoreline per century if one were to consider the loss evenly distributed along the shoreline. The conservative estimate of the total volume of material lost by erosion and introduced into the waters of the Bay system was 270,126,000 cubic yards per 100 years. This is equivalent to a volume one mile square and 165 feet high.

##### 2. Summary of Shore Erosion by Tidal Rivers and Bay Segments

The summary of erosion statistics for the major tidal rivers and segments of the Chesapeake Bay proper are given in Table 2. Although the statistics may be arranged in a number of meaningful ways, only one example is shown here: the ranking of the components with respect to acreage lost per mile of shoreline per century. This treats the information as though the loss has been evenly distributed along the shoreline which is, of course, not the case. It does, however, give some measure of the severity of the problem. Inspection of the table indicates there is most pronounced erosion on the shores of the Bay and that the next most severe erosion is in the wider rivers. This qualitative correspondence would be expected, as the width and orientation of the rivers determines the distance (fetch) over which the winds have to generate waves which are the principal erosion agent.

It should also be noted that some segments of the shoreline have been stabilized by erosion control structures within the time period of our data.

TABLE 1

#### SHORE EROSION STATISTICS FOR THE VIRGINIA CHESAPEAKE BAY SYSTEM

Shoreline Lengths in Statute Miles	
Total Shoreline	2,951
Shoreline Measured for Erosion Characteristics	
Marsh Shoreline	793
Beach Shoreline	1,572
Total Measured	2,365
Shoreline Changes in Acres per 100 Years	
Marsh Shoreline (net)	- 7,361
Beach Shoreline (net)	- 13,718
Total Acreage Lost	- 21,079
Shoreline Changes in Cubic Yards per 100 Years	
Marsh Shoreline (net)	- 57,932,000
Beach Shoreline (net)	- 212,194,000
Total Volume Lost	- 270,126,000

##### 3. Summary of Shore Erosion by Counties and Cities

The summary statistics for shore erosion are given in Table 3A and 3B. Table 3A lists the erosion characteristics by geographical sub-systems and Table 3B arrays the same information according to county or city. Again these results may be arrayed in different ways that are of interest to those involved in managing or planning shoreline use or erosion defenses. One example

is illustrated by Table 4. The counties and cities are listed in descending order with respect to the severity of erosion as reflected by acres lost per mile per 100 years. Inspection indicates that there are fourteen counties which lost at least 10 acres per mile per 100 years. This may be cast in another perspective by considering that a loss of 10 acres per mile per 100 years is equivalent to a recession of 0.8 foot per lineal foot of shoreline per year. Again this characterization considers the recession to be uniformly distributed through time and space, which is not the case.

TABLE 2

#### RANKING OF EROSION BY RIVER SYSTEMS AND BAY SHORES

Chesapeake Bay*	
Southern Shore	- 16 acres/mile/century
Chesapeake Bay	
Eastern Shore	- 12 acres/mile/century
Chesapeake Bay	
Western Shore	- 11 acres/mile/century
Rappahannock River	- 9 acres/mile/century
Potomac River (Va.)	- 7 acres/mile/century
York River	- 6 acres/mile/century
James River**	- 5 acres/mile/century
Piankatank River	- 4 acres/mile/century

\* Lynnhaven Bay system excluded; if included this segment would be very much lower.

\*\* If Chesterfield and Henrico Counties are included the result drops to -0.8 acres/mile/century.

## B. RESULTS FOR INDIVIDUAL SHORELINE REACHES

### 1. Explanation of the Use of Tables for Individual Reaches

To arrive at the erosional history for a particular reach or reaches which encompass the user's area of interest, he should first look at the index map shown in Plate 1. From this index the user determines which map or maps contain his area of interest. For example, assume the user is interested in the erosional history of Gwynn Island in Mathews County. The index map (Plate 1) indicates that Plate (page ) includes Gwynn Island. After turning to that page and locating Gwynn Island, the user must determine two items before obtaining the data relating to the area of interest. He must determine what reach or reaches encompass his area of interest and what system the reaches are in. Let us assume the user is interested in the northeast side of Gwynn Island between Sandy Point and Cherry Point. The reach number assigned this section of Gwynn Island is 326. The system designator is Chesapeake Bay Western Shore. With these two descriptions in mind, the user should then turn to the county data tables which are arranged in alphabetical order according to county. The Mathews County tables are on pages to . The user will note Mathews County has entries for Chesapeake Bay Western Shore and the Piankatank River. After locating this table for Chesapeake Bay Western Shore, he looks down the list of reach numbers until he comes to reach 326. This is the line of information containing the specific data on that reach. The second column in this table is the map number. This map number (8329) does not refer to the plates on which the reach numbers are plotted, but rather refers to maps used in compiling the erosion data. Recall that in this compilation two maps per area were used, one old map and one from the 1940's topographic map series. This map number from the tables (8329) corresponds to the 1940's map number used to compile the erosion data for reach 326. The time spans and maps used in compiling the data for various reaches are listed in Table 5. Examination of Table 5 shows that map 8329 was dated 1942 and that this was compared with map 504; dated 1852. Thus the time span used was 90 years. The next column gives the description of the beginning and end points

of reach 326 as taken from the 1942 topographic map, 8329. Shoreline type, the fourth column, simply states whether reach 326 is marsh (M) or nonmarsh (B). The next two columns, five and six, should be considered together. They list whether reach 326 has undergone erosion or accretion. In the case of reach 326 there has been 283.6 acres of erosion during the time between surveys. Shoreline length, column seven, gives the length of reach 326 in thousands of feet or 19,000 feet. Column eight, mean length, expresses in feet the average distance the shore of reach 326 has retreated or advanced. Reach 326 has retreated 643.7 feet. This figure was arrived at by dividing the acres of erosion or accretion per reach by the shoreline length for that reach. The next column, the rate, expresses a yearly average of the number of feet the shoreline has retreated or advanced. The rate, 7.1 feet per year, was obtained by dividing the mean length 643.7 feet by the time span 90 years. Column ten, height, is the approximate height (5 feet) of the backshore of reach 326. The next three columns should also be considered as a group. Column eleven gives the volume of material lost or gained. Not all maps covered the same time span, thus the volumes listed in column eleven were adjusted to a 100 year span by multiplying by the coefficient to arrive at the adjusted volume. Adjusted volume is then the volume of material lost or gained over this 100 year span. Reach 326 lost 2,539,400 cubic yards of material over this 100 year span.

As a second example let us assume the user is interested in the reaches on Gwynn Island from Sandy Point to Narrows Point. He has located the appropriate Plate (# ) from the index plate, and from Plate determined that reaches 326, 327, 42, 41, and 40 are those of interest. The question then to be answered is, in what system or systems do these reaches fall? As stated previously the Bay and its estuaries are divided into eight systems. In this example the five reaches are cataloged in two systems. Reaches 326 and 327 are in the Chesapeake Bay Western Shore system and reaches 42-40 are in the Piankatank River system. This delineation is noted on Plate by the heavy dashed line connecting Cherry Point and Stingray Point. Thus for Mathews County the reaches up to and including 327 are in the Chesapeake Bay Western Shore system and those from 26-42 are in the Piankatank River system. In this

example the user would then have to look at two Mathews County tables. As before, one would be subtitled Chesapeake Bay Western Shore and the other Piankatank River. The erosional or accretional history from these tables for reaches 327-326, 42-40 would be obtained by the user in the same manner as described in the first example.

TABLE 5

YEAR COMPARISON OF MAPSUSED TO COMPILE REACH NUMBERS
